THE LANCET

Supplementary appendix

This appendix formed part of the original submission and has been peer reviewed. We post it as supplied by the authors.

Supplement to: GBD 2013 Risk Factors Collaborators. Global, regional, and national comparative risk assessment of 79 behavioural, environmental and occupational, and metabolic risks or clusters of risks in 188 countries, 1990–2013: a systematic analysis for the Global Burden of Disease Study 2013. *Lancet* 2015; published online Sept 11. http://dx.doi.org/10.1016/S0140-6736(15)00128-2.

Appendix to: Global, regional and national comparative risk assessment of 79 behavioural, environmental and occupational, and metabolic risks or clusters of risks in 188 countries 1990-2013: a systematic analysis for the GBD 2013

This appendix provides further methodological detail, supplemental figures and more detailed results for the comparative risk assessment.

Appendix A: Methods Overview

Overview

In general, this analysis follows the comparative risk assessment methods used in the GBD 2010.¹ Conceptually, the comparative risk assessment approach evaluates how much of the burden of disease observed in a given year can be attributed to past exposure to a risk. Attributable burden is estimated by comparing observed health outcomes to those that would have been observed if an alternative or counterfactual level exposure had occurred in the past. Given that different risks lead to different health outcomes, assessments are undertaken separately for specific risk-outcome pairs such as high fasting plasma glucose and ischemic heart disease. To the extent possible, each step of this process is standardized to enhance the comparability of results across risks, populations and time.

More formally, for the vast majority of risk-outcome pairs, we estimated the attributable burden using the following equations.

$$AB_{jasct} = \sum_{o=1}^{w} DALY_{oasct} PAF_{joasct}$$
 equ. 1

Where AB_{jasct} is the attributable burden for risk factor j in age group a, sex s, country c and year t. $DALY_{oasct}$ is disability adjusted life years (DALYs) for cause o (of w relevant outcomes for risk factor j) in age group a, sex s, country c and year t. PAF_{joasct} is the population attributable fraction (PAF) for cause o due to risk factor j in age group a, sex s, country c and year t. Attributable deaths, years of life lost (YLLs) or years lived with disability (YLDs) are computed by substituting in the equation these metrics for DALYs.

Risks fall into three categories on the basis of how exposure is measured: dichotomous, polytomous and continuous. Smoking is a dichotomous risk; low physical activity, which has in this analysis four levels, is a polytomous risk and high systolic blood pressure is an example of a risk measured on a continuous scale. The *PAF*_{joasct} for a continuous risk factor in each country is defined as:²

$$PAF_{joasct} = \frac{\int_{x=l}^{u} RR_{joas}(x)P_{jasct}(x)dx - RR_{joas}(TMREL_{jas})}{\int_{x=l}^{u} RR_{joas}(x)P_{jasct}(x)dx} \quad equ. 2$$

 $RR_{joas}(x)$ is the relative risk as a function of exposure level x for risk factor j, cause o, age-group a and sex s. l is the lowest level of exposure and u is the highest level of exposure observed. $P_{jasct}(x)$ is the distribution of exposure for risk j in age-group a, sex s, country c and year t. $TMREL_j$ is the theoretical minimum risk exposure level for risk factor j, age group a and sex s. The PAF_{joasct} for dichotomous and polytomous risk factors for every country is defined as:

$$PAF_{joasct} = \frac{\sum_{x=1}^{u} RR_{joast}(x)P_{jasct}(x) - RR_{joas}(TMRE_{jas})}{\sum_{x=1}^{u} RR_{joast}(x)P_{jasct}(x)} \quad equ. 3$$

The equations highlight the four key components by cause, age, sex, country and year that go into estimating the burden attributable to a risk factor: the number of deaths, YLLs, YLDs or DALYs; exposure levels for a risk factor; relative risk of a given outcome due to exposure; and the counterfactual

level of risk factor exposure. In the comparative risk assessment approach, the counterfactual level of risk exposure is selected to be the risk exposure that is theoretically possible and minimizes overall risk (Theoretical Minimum Risk Exposure Level [TMREL]).³ The intention is to quantify how much disease burden could be lowered by shifting the distribution of a risk to the level that would lead to the greatest improvement in population health. The GBD 2013 provides the rates of mortality, YLLs, YLDs and DALYs by cause.^{4,5} Here we focus on the data and methods used to estimate for 79 behavioural, environmental/occupational, and metabolic risks and clusters of these risks, levels of exposure, relative risks and the choice of TMREL.

For unsafe sex and occupational injuries we did not use the attributable burden formulas described above. For intimate partner violence and drug use the burden formulas above are used for some but not all outcomes. These exceptions stem from the nature of the available data and are explained in more detail in Appendix B.

Risk factor hierarchy

In this analysis, we focus on three groups of risk factors: behavioural, environmental/occupational and metabolic. Figure 1 shows a more complete causal web which recognizes the role of four other sets of risks: genes, the microbiome and other host factors, public health and medical care interventions, and social, economic and cultural factors. It is currently beyond the scope of this study to quantify these other categories of risks or causes; however, in future iterations of the GBD we intend to broaden the analysis to include at least some of these broader causes. As the figure is illustrative of the greater complexity in examining a broader set of causes of health outcomes, all the arrows detailing possible interconnections have not been drawn.

For the current assessment focused on behavioural, environmental/occupational and metabolic risk factors, risk-outcome pairs have been included based on four criteria. The criteria for inclusion of risk-outcome pairs take into account the importance of each risk factor to either disease burden and/or policy; the availability of sufficient data to estimate risk factor exposure; evidence from epidemiological studies supporting a causal relationship between risk factor exposure and the outcome and available data to estimate effect sizes per unit of exposure increase; and evidence that these effects can be generalized to a general population. Following the GBD 2010, we have adopted the World Cancer Research Fund grading of evidence supporting the causal relationship between risk factor exposure and an outcome. They defined four levels of evidence: convincing, probable, possible and insufficient. Only risk-outcome pairs judged to meet the criteria of convincing or probable were included.

The World Cancer Research Fund grading system

Convincing evidence

Evidence based on epidemiological studies showing consistent associations between exposure and disease, with little or no evidence to the contrary. The available evidence is based on a substantial number of studies including prospective observational studies and where relevant, randomized controlled trials of sufficient size, duration, and quality showing consistent effects. The association should be biologically plausible.

Probable evidence

Evidence based on epidemiological studies showing fairly consistent associations between exposure and disease, but for which there are perceived shortcomings in the available evidence or some evidence to the contrary, which precludes a more definite judgment. Shortcomings in the evidence may be any of the following: insufficient duration of trials (or studies); insufficient trials (or studies)

available; inadequate sample sizes; or incomplete follow-up. Laboratory evidence is usually supportive. The association should be biologically plausible.

Possible evidence

Evidence based mainly on findings from case-control and cross-sectional studies. Insufficient randomized controlled trials, observational studies, or non-randomized controlled trials are available. Evidence based on non-epidemiological studies, such as clinical and laboratory investigations, is supportive. More trials are needed to support the tentative associations, which should be biologically plausible.

Insufficient evidence

Evidence based on findings of a few studies which are suggestive, but insufficient to establish an association between exposure and disease. Little or no evidence is available from randomized controlled trials. More well-designed research is needed to support the tentative association.

Six new risk factors met our criteria for the GBD 2013: handwashing practices, occupational exposure to trichloroethylene, childhood wasting, childhood stunting, unsafe sex, and low glomerular filtration rate. In addition, we included six clusters of risks factors that were not computed in GBD 2010.

Table 1 summarises the included risk factors; there are, counting risks and clusters of risks, 79 different risks in the hierarchy. At Level 2 of the hierarchy, we have 13 groupings of related risks. At the most detailed level in the hierarchy, we have 63 individual component risks, and the other 16 entries in Table 1 are different aggregations of risk factors. We have in the GBD 2013 included quantification of each of the Level 1, Level 2 and Level 3 groupings and an overall estimate of all risk factors combined. Joint risk computation for some of these clusters of risks requires addressing issues of risk mediation and exposure correlation which are addressed below.

New risk-outcome pairs were added for risks already included in the GBD 2010 due to new evidence and some risk-outcome pairs were excluded because they did not meet the quality of evidence criteria. We included hemorrhagic stroke, liver cancer, ovarian cancer, leukemia, and thyroid cancer as outcomes of high body-mass index after an updated meta-analysis showed a statistically significant association with elevated body-mass index.⁶ We added morbidity of injuries to occupational risk factors. A Ugandan cohort study provided more evidence in addition to a South African cohort study that was available at the time of GBD 2010 to allow the addition of HIV as an outcome of intimate partner violence.²² We added lower respiratory infection in adults to smoking, secondhand smoking, outdoor and household air pollution. Several studies showed an increase in pneumonia hospitalization related to high ambient concentration of particles with diameter smaller than 2.5 microns (PM2.5 levels). 9-14 We used a relative risk of smoking on lower respiratory infection from the physicians' cohort study in the integrated exposure-response curve which enabled us to predict the level of risk for other sources of PM2.5 including air pollution, secondhand smoking, and household air pollution. ¹⁵ Typhoid and paratyphoid fever were removed as outcomes of zinc deficiency and vitamin A deficiency due to a lack of explicit evidence. Malaria was removed as an outcome of underweight because an updated meta-analysis found no significant association. ¹⁶ Web Table 4 provides the complete list of risk-outcome pairs in this study.

Estimating risk factor exposure

Data and exposure categories

For each risk factor exposure, a similar approach has been used to identify potential data sources. Our analyses for the GBD 2013 of tobacco smoking prevalence and obesity have been published. For all risk factors, we have sought to identify and use published studies through systematic reviews of the literature, household survey data, census data and satellite data (used for PM2.5 estimation). For some risks such as diet and alcohol consumption, we have also used administrative record systems. We began with the GBD 2010 sources that were identified and supplemented those by updating literature searches and identifying surveys, censuses, and administrative data. Web Table 5 provides citations for all sources used for estimating risk factor exposure organized by country and within country by risk factor.

We have computed a data representativeness index (DRI) for risk factor exposure estimation. The DRI for a risk factor is the fraction of countries for the relevant time period for which we have identified any data on the risk factor. Table 1 provides the DRI for the entire period 1985-2013 and the DRI calculated for three intervals: pre 1997, 1998-2005 and from 2006 onwards. The time period DRI helps identify which periods have more sparse data. The overall DRI ranges from 17% for diet low in polyunsaturated fatty acids to 100% for ambient ozone pollution and ambient particulate matter pollution. The DRI for PM2.5 is 100% because data are available for all countries and all years, although direct satellite observations are unavailable before 1998. We should note that 4105 unique site years were available to calibrate the satellite data. While the DRI for household air pollution is 94%, it is important to note that the actual exposure variable used is fuel type used in the household and not a direct measurement of PM2.5 in the house. Other examples of proxy measurement of exposure include: living with a smoker as proxy to exposure to secondhand smoke, the estimated zinc content of the national food supply in comparison with theoretical physiological requirements as proxy for zinc deficiency, the smoking impact ratio as proxy for cumulative tobacco smoke exposure, and a similar approach for the asbestos impact ratio as a proxy for exposure to asbestos. 19,20 While in other cases, more direct measures of exposure have been used these also have measurement error associated with them.

For water and sanitation, the exposure categories have been modified for GBD 2013. In GBD 2010, the Joint Monitoring Project categories of access to improved and unimproved water and sanitation facilities were used as dichotomous exposures.²¹ However, the meta-regression of interventions for both water and sanitation indicated that the improved categories were not minimum risk categories.²² For water the facility type associated with minimum risk was piped connection to households, while sewer connected toilets were associated with lowest risk for sanitation. We have elaborated the categories estimated for water to include household use of water treatment methods in addition to the traditional measure of the type of drinking water source used. For sanitation, also based on the same logic, we have modified the exposure categories to reflect the prevalence of access to sanitation facilities with and without connection to sewer or other technology removing excreta from the community.

Similar to childhood underweight, the exposure distribution of both childhood stunting and wasting were generated from a systematic analysis of available anthropometric data from censuses, health examination and nutrition surveys, and published epidemiological studies using the 2006 WHO Child Growth Standard.

For injecting drug use, the exposure definition was changed from current exposure to ever-exposed to injecting drug use to more accurately capture the relationship between injecting drug use and hepatitis B and C.

Modeling strategies for exposure levels

Web Table 3 lists the modeling strategy used for estimating exposure for each risk factor. For 23 risks, we used DisMod-MR 2.0 which is a Bayesian meta-regression method used extensively in estimating the prevalence of diseases for the GBD 2013. See Vos et al for a detailed description of the likelihood used for estimation and an explication of improvements in DisMod-MR 2.0 compared to DisMod-MR 1.0 used in GBD 2010.⁵ In brief, DisMod-MR 2.0 demonstrates improvements over DisMod-MR 1.0 in computational speed, geographic disaggregation, and display capabilities. The advantage of DisMod-MR 2.0 is that it estimates both the age-sex pattern of a risk as well as different levels over time based on estimation for 1990, 1995, 2000, 2005, 2010 and 2013. For 12 risk factors modeled using DisMod-MR 2.0, we conducted cross-validation tests. We used two metrics of the performance of models in terms of predictions for data held out of the model estimation: the root-mean squared error of the predictions compared to the data and the percentage of the time the prediction 95% interval includes the data held out. Based on both metrics, the modeling strategies were appropriate (Web Table 6).

For 34 risks, we used spatio-temporal Gaussian process regression (ST-GPR) which was also used for multiple risk factors in GBD 2010. ST-GPR has been used for risk factors where the data density is sufficient to estimate a very flexible time trend that does not vary over age. If the tabulated data were in standard age groups or was at the household level, such as access to different levels of improved water and sanitation or exposure to radon or available zinc intake, we used ST-GPR, but if the data were available by different age intervals, or mixed sex groups, we used DisMod-MR 2.0 because of its ability to integrate over age and adjust for different exposure definitions in the data. In GBD 2010, a different Bayesian hierarchical model was used to model time trends in body-mass index, blood pressure, cholesterol and fasting plasma glucose. To assess the accuracy of our estimates and to compare our results with Bayesian models similar to the ones used in GBD 2010, we carried out cross-validation by randomly holding out 20% of the sample from the measured data, 10 separate times. We specifically held out measured data as they were considered as the "gold-standard." We computed the average root mean squared errors (RMSE). The results are shown in Web Table 1.

Web Table 1. Comparisons of in-sample and out-of-sample RMSE between Bayesian Models and ST-GPR for body-mass index, cholesterol, fasting plasma glucose, and systolic blood pressure

	RMSE for training set		RMSE for test set	
	Bayesian Models	ST-GPR	Bayesian Models	ST-GPR
Body-mass index	1.622	0.609	1.583	0.860
Cholesterol	0.304	0.242	0.321	0.307
Fasting plasma	0.345	0.294	0.359	0.371
glucose				
Systolic blood	5.686	4.385	5.834	5.185
pressure				

The performance of spatiotemporal Gaussian Process Regression (ST-GPR) in terms of RMSE for both training and test sets are overall superior to the Bayesian model. For the training sets, the difference in RMSE ranged from 0.05 to 1.3, with ST-GPR consistently yielding the smaller RMSEs. As for the test sets, the difference in RMSE ranged from -0.012 to 0.723 with ST-GPR generally yielding better out-of-sample prediction results.

 $RR_{joas}(x)$ is the relative risk as a function of exposure level x for risk factor j, cause o, age-group a and sex s. l is the lowest level of exposure and u is the highest level of exposure observed. $P_{jasct}(x)$ is the distribution of exposure for risk j in age-group a, sex s, country c and year t. $TMRE_{jas}$ is the theoretical minimum risk exposure level (TMREL) for risk factor j, age group a and sex s.

For PM2.5, estimates of annual concentrations were generated by combining data from atmospheric chemistry transport models and satellite retrievals of aerosols in the atmosphere. These measurements were generated at the level of grid cells with 0.1° x 0.1° resolution, equivalent to approximately 11km x 11km at the equator. The combined PM2.5 concentrations were then calibrated against observations from ground-level monitoring of particles from more than 75 countries. The calibration equations was estimated using 4073 ground measurements of annual average concentrations including significant interaction terms for quality and accuracy of location of ground monitors. Country estimates of PAFs for every outcome were generated by taking a population-weighted average of relative risks based on the exposure at each grid level.

For iron deficiency, exposure is expressed as the mean hemoglobin level for each age-group, country, sex and year. Data on mean hemoglobin were obtained primarily from Demographic and Health Surveys (DHS) and the World Health Organization (WHO) Vitamin and Mineral Nutrition Information System (VMNIS). We estimated mean hemoglobin for every unit of estimation (country, year, age, sex) using a mixed-effects regression with a fixed effect on prevalence of severe underweight (<2 standard deviations below mean), and nested random effects on super-region, region, and country/subnational site. See Vos et al for a detailed description of the estimation process and data sources.⁵

For modeling burden attributable to tobacco smoking, we used the smoking impact ratio (SIR) developed by Peto, Lopez and colleagues for cancers and chronic respiratory disease such as chronic obstructive pulmonary disease, and interstitial lung disease, and 5-year lagged smoking prevalence for all cardiovascular outcomes, tuberculosis, diabetes and asthma. SIR is commonly used to reflect past exposure, duration and intensity of smoking and is calculated as the population lung-cancer mortality in excess of never-smokers, relative to excess lung-cancer mortality in a known reference group of smokers. ^{32,40} Non-smoker lung cancer mortality rates can vary by age, sex and country. For all countries we assumed the same rate of lung cancer in never smokers as observed in CPS-II, CPS-I, the Multiethnic Cohort (MEC), Health Professional's Follow-up Study (HPFS), Black Women's Health Study (BWHS), Nurses' Health Study (NHS), and Women's Health Study (WHS), except in Asian regions where local data on age-sex specific never smoker lung cancer rates were available to reflect different baseline nonsmoker lung cancer rates due to factors such as solid fuel use of coal and biomass. 41-43 Cohorts in different Chinese provinces, including the China Kadoorie Biobank (CKB) study from 2006-2011, were used to model non-smoker lung cancer rates in China. For Asia-Pacific high-income countries, the Korean Cancer Prevention Study (CPS) and the Three Prefectures Study provided lung cancer mortality rates in never smokers.³⁰ We applied the results from these 13 Asia-Pacific high-income cohorts to countries in the regions of East Asia, South Asia, and Southeast Asia, based on known regional similarities in nonsmoker lung cancer rates that differ markedly from never smoker rates from CPS-II.

For every country c; age-group a; sex s; year t; SIR is calculated by this formula:³¹

$$SIR_{casy} = \left(\frac{L_{casy} - L_{casy}^{N}}{L_{casy}^{S*} - L_{casy}^{N*}}\right) \left(\frac{L_{casy}^{N*}}{L_{casy}^{N}}\right) \quad equ. 4$$

Where:

L: observed lung cancer mortality rate

L^N: lung cancer mortality rate in non-smokers for the country

L^{N*}: lung cancer mortality rate in never smokers in the reference population (CPSII)

L^{S*}: lung cancer mortality rate in smokers in the reference population (CPSII)

The prevalence of current alcohol drinkers (any drink during past 12 months), former drinkers and lifetime abstainers was estimated in DisMod-MR 2.0 using country survey data and rescaled to 100% by country, year, age and sex. Per capita consumption figures are considered to be a better estimate of overall volume of consumption as surveys often underestimate real consumption levels.^{30,32} Data on alcohol consumption per capita were obtained from the FAO and the WHO Global Information System on Alcohol and Health (GISAH) to model exposure for alcohol consumption.³³ The data are adjusted using a correction factor from WHO to account for unrecorded consumption; while alcohol consumption results have been published, details on the empirical basis for the unrecorded consumption correction, however, have not been published by WHO. ST-GPR was used to integrate the data and to derive coherent time series for each country – see Freeman et al for details. 34,35 DisMod-MR 2.0 was used to estimate mean alcohol consumption in current drinkers by age, sex, country and year from available survey micro-data (listed in the Web Table 5). The mean consumption at each age and sex was then scaled up to 80% of the ratio of the country's total consumption and the implied total consumption in drinkers from survey data. The 80% factor accounts for spillage, wastage and breakage. The standard deviation for each upscaled mean value of consumption was estimated from a linear regression with standard deviation as the dependent variable and mean and sex as the independent variables in the global data set of alcohol consumption data. The upscaled mean and standard deviations were then used to fit a gamma distribution of the amounts of alcohol consumed in each age, sex, year and country category. 36,37

A protective effect of alcohol on cardiovascular disease was only considered in people who do not binge drink. We defined the proportion of current drinkers who are binge drinkers as anyone reporting one or more instances of having consumed 48 grams of alcohol in a single occasion for females and 60 grams of alcohol in a single occasion for males in the past year. Separately, we model the proportion of days in a year that survey respondents report binge drinking in DisMod-MR 2.0. We multiply the proportion of binge drinkers with the proportion of binge days in a year by age, sex, country and year and exclude the average time that drinkers are bingeing from the estimation of the protective effect of alcohol on cardiovascular outcomes. In DisMod-MR 2.0 we crosswalk data with recall periods of one week and one month to the values of a one year recall period. For injuries, we separately estimate risk for the amount of time at risk during binge events and that for non-binge drinking. For bingers, we multiply the proportion who binge drink by the average number of binges in a year and from the average number of drinks during a binge we estimate the proportion of time spent at risk using an established relationship between alcohol intake at different levels and the corresponding blood alcohol level. After subtracting the amount of alcohol consumed during binge events from a country's total consumption, the amount of time at risk is also calculated in non-binge drinkers.³⁸

To estimate the distribution of low physical activity, we modeled activity level in metabolic equivalent (MET) minutes/week (ratio of metabolic rate during a specific physical activity to a resting metabolic rate). The standard definition was any activity performed for work, transport, recreation or house/yard work, measured using the International Physical Activity Questionnaire (IPAQ).³⁹ We also included survey data that used the Global Physical Activity Questionnaire (GPAQ).⁴⁰ However, domestic physical activity is not explicitly captured by the GPAQ domains so we corrected figures using this alternative definition for females, based on empirical evidence that the GPAQ underestimates overall activity for women in low-income countries. As the older surveys only report categorical data we decided to categorise the newer survey data rather than use it as a continuous variable. The proportion of the

population in each of four categories of activity level (inactivity: <600 MET-minutes/week; low activity: 600-3999; moderate activity: 4000-7999; and highly active: >8000) were modeled separately, then rescaled to sum to one.

Exposure to occupational risks was estimated using data from labour force surveys and censuses on the economically active population available from the International Labor Organization (ILO). The distribution of the economically active population across nine industries or eight occupational groups was used to measure exposure to occupational asthmagens, particulate matter, noise, and ergonomic factors. The choice of distribution across industries or occupational groups was made based on the exposure groups defined in the corresponding relative risk estimates. The cumulative exposure to occupational carcinogens was estimated by taking into account the proportion of employees leaving the occupational category in a year in addition to the distribution of the economically active population for each country. To measure exposure to occupational asbestos, we use a method analogous to the smoking impact ratio, where the number of mesothelioma deaths, generated from the GBD cause-specific mortality estimates, was used as a marker of asbestos exposure. Specifically, the asbestos impact factor is defined as the observed mesothelioma death rate minus the mesothelioma death rate in the absence of asbestos exposure in the population. Since occupational exposure is an important source of exposure to asbestos, we categorised this under occupational hazards albeit this method captures exposure to every source of asbestos. Too few data are available on the sources of asbestos to make separating occupational from nonoccupational exposure possible.

To calculate the burden of each continuous risk factor, the distribution of exposure needs to be estimated, which includes central tendency and dispersion parameters. We modeled mean and standard deviation in each country-age-sex group because almost all studies summarize the distributions by reporting the mean (or median) and standard error from which standard deviation can be calculated. In GBD 2010, for computational simplicity, all continuous risks were assumed to be normally distributed, so mean and standard deviation were used to simulate the population distribution in the PAF calculation. Considerable evidence suggests most risks are not normally distributed.³⁶ For GBD 2013, we have devoted substantial effort to modeling standard deviations and choosing appropriate distribution for each risk factor. First, to estimate standard deviations for each risk in each country, age, sex group, we modeled the natural log of the standard deviation using observed data as a function of the mean and fixed effects on risk and super-region.

To generate standard deviation DisMod-MR draws for dietary risk factors, we modeled the relationship between standard deviation and mean with fixed effects on risk factor and super region:

ln (Standard deviation) =
$$\beta_0 + \beta_1 x \ln (Mean_i) + \beta_{risk} x I_{risk} + \beta_{super region} x I_{super region} + \epsilon_i$$
 equ. 6

We used standard deviations and means from dietary survey data from adults aged 25 and older to derive the regression coefficients above. The beta coefficients were then applied to draws of mean intake from DisMod-MR 2.0 to generate draws of standard deviation for each dietary risk factor. See Vos et al for a detailed description of DisMod-MR 2.0 compared to DisMod-MR 1.0 used in The Global Burden of Disease study (GBD) 2010.⁵

Second, we evaluated the likelihood value of fitting normal, lognormal, gamma, beta and inverse Gaussian distributions to the United States National Health and Nutrition Examination Survey (NHANES) micro-data on systolic blood pressure, body-mass index, fasting plasma glucose, and cholesterol. Ultimately, we assigned continuous risk factors into three distribution groups: normal, lognormal and beta. We assumed a lognormal distribution for systolic blood pressure, cholesterol, fasting plasma glucose, diet low in fruits, diet low in vegetables, diet low in nuts and seeds, diet low in milk, diet

low in whole grains, diet low in fiber, diet low in calcium, diet low in seafood omega-3 fatty acids, diet high in red meat, diet high in processed food, diet high in saturated fat, diet high in trans fatty acid, diet high in sodium, and diet high in sugar-sweetened beverages, which was successfully able to handle the asymmetrical shape and variance reported by studies in normal distribution. The three exceptions to lognormal distribution were iron deficiency and low bone mineral density (NHANES data showed that normal distribution had better fit to the left tail, that causes osteoporosis burden, than lognormal distribution) in which a normal distribution was used and high body-mass index in which we used a beta distribution where body-mass index is first transformed to be on a 0 to 1 scale and the alpha and beta parameters for the distribution are fit to the mean and standard deviation with the constraint that skewness cannot be negative. While no statistical distribution (testing included normal, beta, lognormal, inverse Gaussian, gamma) had a good fit to the fat tail of fasting plasma glucose in NHANES, lognormal showed the best fit by the likelihood value among those tested.

Relative risks for systolic blood pressure have been corrected for regression dilution bias.⁴¹ This is because measured blood pressure on a given day is not the same as usual blood pressure because individual blood pressure varies over time. In order to make the systolic blood pressure estimates consistent with the adjusted relative risks for regression dilution bias, we have corrected exposure standard deviations for a measure of intertemporal variance in blood pressure observed in cohort studies – see Appendix B for details. This effectively ensures that our figures reflect usual systolic blood pressure.

Estimating the effects of risk factors on disease and injury outcomes

For 59 risk factors, where we estimate attributable burden using the relative risk and exposure formula, we estimated relative risks of mortality and morbidity based on either published meta-analyses, meta-analyses updated with new studies, or new meta-regressions which include covariates such as age, sex, or country level predictors for the GBD 2013.

For every risk factor, relevant outcomes meeting the World Cancer Research Fund criteria of convincing or probable evidence for a causal association were identified. We used almost all outcomes from 2010 and added 35 pairs to them through a comprehensive review of the list after a call for all GBD collaborators to suggest new risk-outcome pairs. New risk-outcome pairs include handwashing practices – diarrhoeal diseases, typhoid fever, paratyphoid fever; occupational exposure to trichloroethylene – kidney cancer; childhood wasting – diarrhoeal diseases, lower respiratory infections, measles, protein-energy malnutrition; childhood stunting – diarrhoeal diseases, lower respiratory infections, measles; smoking – lower respiratory infections; diet low in nuts and seeds – diabetes mellitus; diet high in sugar-sweetened beverages – liver cancer, ovarian cancer, thyroid cancer, leukemia; intimate partner violence – HIV/AIDS; unsafe sex – HIV/AIDS, syphilis, chlamydial infection, gonococcal infection, trichomoniasis, genital herpes, other sexually transmitted diseases, cervical cancer; high body mass index - hemorrhagic stroke, liver cancer, ovarian cancer, thyroid cancer, leukemia; low glomerular filtration rate – ischemic heart disease, cerebrovascular disease, peripheral vascular disease, chronic kidney disease, and gout. For risk-outcome pairs where evidence is only available on either mortality or morbidity, we assume that the estimated relative risks were applied equally to both. Where there was evidence of statistically different relative risks for mortality and morbidity, we used different relative risks for each. Of note in these cases, there was not consistent pattern where relative risks were higher or lower for mortality compared to morbidity. Web Table 7summarises the relative risks used by age and sex for each risk factor and outcome pair and Web Table 8 provides citations for all sources used for relative risks. Separate entries are provided where the risks are different for mortality and morbidity. We use relative risks from studies controlled for confounding but not controlling for factors along the causal pathway between exposure and outcome.

We used an updated meta-regression for water, sanitation, and handwashing with results from recently published studies. ^{22,42} We conducted a new meta-regression for physical activity by converting the activity levels for which relative risk data are available to total MET minutes of activity per week. DisMod-MR 2.0 was used to generate a continuous risk curve for each outcome as a function of MET-minutes activity per week.

We updated the relative risks for childhood underweight using a recently published study that conducted a pooled analysis of children enrolled in 10 prospective cohorts in Africa, Asia, and South America.⁴³ The same analysis was used to derive the relative risks for outcomes associated with childhood stunting and wasting. The updated effect sizes for all outcomes except malaria reported by Olofin et al are higher than those previously reported.⁴⁴ The updated relative risks for all three anthropometric indicators showed that they have no significant effect on malaria. Finally, we assumed that 100% of the burden of protein-energy malnutrition was attributable to childhood underweight and wasting.

We updated the meta-analysis of the relative risks for body-mass index and all of the site-specific cancers, incorporating new evidence that has come out since GBD 2010.⁴⁵ We used an updated meta-analysis of relative risks for alcohol and ischemic heart disease and stroke.⁴⁶ For dietary risks, new meta-analyses were used to update relative risks for the following risk-outcome pairs: fruits and mouth, larynx, nasopharynx, and larynx cancers; whole grains and diabetes; nuts and seeds and ischemic heart disease; nuts and seeds and diabetes; whole grains and ischemic heart disease; and polyunsaturated fatty acids and ischemic heart disease.^{47–49}

The integrated exposure-response curve was used as a framework for ambient particulate matter pollution, household air pollution, secondhand smoke, and tobacco smoking in GBD 2010.⁵⁰ For GBD 2013, we reestimated these relationships using recently published studies of relative risk and also extended their use to estimating the burden from secondhand smoke and household air pollution for COPD.^{50–58} We tested different functional forms and confirmed that a monotonically increasing non-linear function of three parameters representing the rate of change in risk with concentration, the power of concentration, and the maximum allowable risk had the best fit to the available studies; we used Markov Chain Monte Carlo methods to solve this non-linear equation. This configuration allowed each outcome to be characterized by a different shape as represented by the available information on risk. Uncertainty in risk predictions was captured by the uncertainty in estimates of the model parameters.

In some cases, evidence on the direct relationship between a risk factor and a disease outcome was lacking or extremely sparse. For three risk factors (lead, sugar-sweetened beverages, and high sodium), we estimated relative risks through a two stage process. For example, for salt, we first estimated the relationship between 24-hour sodium excretion and change in systolic blood pressure. Second, we estimated the relationship between change in blood pressure and disease outcomes to estimate the impact of salt on outcomes. This approach was also used for chronic lead exposure on adults (impact of bone lead through blood pressure) and sugar-sweetened beverages (through body-mass index). Where this has been undertaken, the relative risks reflect uncertainty from both stages of the analysis by keeping 1000 draws from each step to estimate posterior distribution of mediated relative risk.

Convincing evidence to support a causal association requires a reliable and statistically significant association between a risk factor and outcome. However, when using a wide body of evidence to generate age- and outcome-specific relative risks we encountered measures of effects with 95% confidence intervals that spanned 1.0 in multiple age groups or across different levels of exposure. In order to use the wide body of evidence and to fully account for the uncertainty associated with all of the subgroups, we included draws that show a protective effect as long as the overall association across all age groups and

exposure categories is significant. In the case of risk factors with some non-significant relative risks across different levels of exposure, relative risks were included only if the mean values showed a consistent relationship. Finally, alcohol and high body-mass index are the only risk factors included in our current analysis that show a significant protective effect for selected outcomes; and the protective effects are restricted to certain groups (i.e. pre-menopausal women for high body-mass index) or levels of intake (i.e. alcohol). This inclusion is based on the known evidence for the protective effect of alcohol consumption on ischemic heart disease among non-binge-drinking current drinkers. Recent studies confirmed previous meta-analyses which indicated a protective effect of high body-mass index on breast cancer in premenopausal women outside of Asia-Pacific countries. We used a relative risk of less than one and estimated the reduction in the burden of breast cancer in premenopausal women in all countries except South Asia, East Asia, South-East Asia, and high-income Asia-Pacific due to high body-mass index. We also used a relative risk less than one for alcohol and ischemic heart disease, ischemic stroke, and diabetes mellitus.

Theoretical minimum risk exposure level (TMREL)

In the comparative risk assessment framework, attributable burden is calculated with respect to a counterfactual risk exposure – see equation 2. In the GBD 2010, we used the exposure distribution that minimizes risk for the population, termed the theoretical minimum risk exposure distribution (TMRED).³ Based on a consultation with risk factor epidemiologists, we have chosen to simplify the TMRED and to choose a single level of risk exposure that minimizes risk from all causes of DALYs combined which we term the theoretical minimum risk exposure level (TMREL). The distinction is that the minimum risk level has no standard deviation whereas the TMRED had a standard deviation for continuous risks but not for dichotomous risks. To maximize comparability across dichotomous, polytomous and continuous risks and to enhance the ease of communication, we have opted to choose the single minimum risk exposure level (TMREL). The TMREL by its definition should minimize individual (and population level) risk and be theoretically possible to achieve, but not necessarily affordable or feasible to achieve. Table 1 shows the TMREL for each risk factor. For tobacco, it is 100% of the population being lifelong nonsmokers. In some cases, such as sodium consumption, the evidence supporting the selection of the TMREL is uncertain. In these cases, we include in the uncertainty estimation sampling a uniform distribution of different TMRELs. Where an uncertainty interval (UI) has been used, Table 1 provides the range and distribution of the uncertainty in the TMREL.

As part of the GBD 2013, we have re-reviewed the TMREL for each risk factor. In GBD 2010 for some risks such as water and sanitation, the TMRED was defined as improved water and improved sanitation, which given the results of the meta-regression, is not theoretical minimum risk. We have modified the TMREL to be households with piped water connections and those who also boil or filter their water before drinking for unsafe water. Similarly, the TMREL for unsafe sanitation now is defined by proportion of households that have access to sewer connected toilet facilities.

For childhood underweight, the observed minimum risk distribution of the WHO 2006 reference population in each standard deviation range was assumed to be the TMRED in GBD 2010. However, the revised TMREL that minimizes individual and population level risk for childhood underweight along with stunting and wasting is defined by assuming that all children under the age of five lie above -1 standard deviation of the WHO 2006 standard weight-for-age, height-for-age, and weight-for-height curves respectively.

In GBD 2010, a TMRED with a mean of 1 gram per day of urinary sodium excretion was used for sodium intake. This value was supported by randomised clinical trials (RCTs) which found that systolic blood pressure falls continuously as sodium is lowered to levels as low as 1 gram per day.⁶⁵ The Institute of Medicine 2013 report *Sodium Intake in Populations Assessment of the Evidence* argued that the evidence for benefit for lowering sodium below 2.3 grams/day was unclear.⁶⁶ The PURE cohort study, found a J-shaped association between urinary sodium excretion, mortality and major cardiovascular events, with minimum risk of death and major cardiovascular events observed between 3 and 6 grams of sodium excretion per day.⁶⁷ Taking into account the potential overestimation of the Kawasaki formula used to estimate Na excretion in PURE, the upper bound of minimum risk appears closer to 5 grams per day. To account for the scientific uncertainty surrounding the level of sodium that most minimizes risk, we sampled a uniform distribution ranging from 1 to 5 grams per day to generate the TMREL. This choice, however, was controversial across the GBD investigators with a number of diet collaborators proposing an uncertainty interval of 1-3 grams per day; the GBD Scientific Council made the final decision following the GBD Study Protocol to use an uncertainty interval of 1-5 grams per day.

For diet, the TMRED in GBD 2010 was assumed to have no uncertainty. However, the evidence for the level below (or above) which risk is no longer reduced is in many cases uncertain; to reflect this we have assumed a uniform uncertainty distribution of 20% above and below the mean. Studies have shown tapering off of relative risk across a range of intake levels for various dietary components. ^{68,69}

For bone mineral density, we used the 99th percentile of age-sex subgroups of US National Health and Nutrition Examination Survey (NHANES) III studies between 2005-2010 data instead of 90th percentiles from NHANES III (used in GBD 2010). Using the 99th percentile enables us to consider the bone density decrease by age while capturing the excess risk of fracture caused by lower bone mineral density observed in elderly populations. Because cause of death data report by external cause and not nature of injury, for attributing mortality to low bone mineral density, we calculated intra-hospital deaths due to fractures as a proportion of all deaths from each cause of injury category. Estimating potentially fatal fractures linked to low bone mineral density had two components. First, we examined only hip, vertebral, pelvis, rib, skull and femur fractures as other fractures were unlikely to be the true cause of death. Second, to avoid over-estimation, we excluded deaths with fractures but where more serious injuries were also reported. The list of more serious injuries excluded in GBD 2010 was traumatic brain injury and internal organ damage. For this study, this list has been extended to include burns greater than 20% body surface, lower airway burns, amputations of lower limb, amputations of upper limb, drowning, asphyxiation and poisoning.

Attributable burden estimated using other approaches

For unsafe sex, and occupational injuries for all outcomes, we did not use the relative risk and exposure method to estimate attributable burden. Due to lack of reliable relative risk estimates associating different occupations with injury outcomes, we used data on rates of fatal injuries by industry reported as related to their occupation to calculate the PAF. This implicitly assumes that the TMREL would be zero occupation related fatal injuries.

Given the difficulty of fitting unsafe sex in the exposure-risk framework, we took a direct attribution approach and modeled the PAFs directly in DisMod-MR 2.0. For HIV, we extracted data from sources that reported the number of newly diagnosed cases of HIV that could be traced to sexual transmission routes to directly model the proportion of HIV attributable to unsafe sex, as well as the proportion attributable to injecting drug use and other modes of transmission. We modeled the proportion of homicides due to intimate partner violence directly as well. For other sexually transmitted diseases and

for cervical cancer, the attributable fraction from unsafe sex was set to 100 percent, due to all of these outcomes stemming from unsafe sexual contact. To estimate the burden of HIV attributable to intimate partner violence (IPV), we used a cohort method whereby HIV risk associated with past exposure to IPV is accumulated over time. The proportion of HIV morbidity and mortality due to IPV is approximated by the ratio of cumulative IPV-attributable HIV incidence to total HIV incidence, accrued every year after age 15 up to the year and age group of interest. The IPV-attributable HIV incidence figure in the numerator is calculated using the traditional PAF equation with an incidence rate ratio as the metric for HIV risk born by IPV exposure. A similar method was used to estimate burden of Hepatitis B and Hepatitis C attributable to injecting drug use.

Burden attributable to clusters of risk factors

There is interest in what fraction of the burden of disease is attributable to various combinations of risk factors or to all risk factors combined. In the GBD 2010, the burden attributable to various clusters of risk factors were reported; however, joint estimates were not produced for metabolic risk factors, air pollution, and all risk factors combined. The burden of disease attributable to other clusters of risk factors was computed assuming the action of each risk factor was independent of the other and the exposure to each risk factor was uncorrelated within each age-sex-country-year. To compute the joint risk factor burden for metabolic risks and combinations of metabolic risk factors with other behavioural or environmental risk factors requires assumptions about how one risk factor is mediated through other risk factors; for example, what fraction of the hazard associated with obesity is mediated through blood pressure or cholesterol?

A detailed explanation of the aggregation process and mediation adjustment is provided in the next section of the Appendix, "Risk factor aggregation and challenges of mediation". Briefly, since the publication of the GBD 2010, Danaei et al have examined the mediation of elevated body-mass index risk through blood pressure, cholesterol and fasting plasma glucose and showed that a significant part of high body-mass index risk can be explained/mediated through other metabolic risk factors. 72 The amount of the mediated effect for body-mass index through cholesterol was calculated by the ratio of the amount of the difference between the crude and adjusted relative risk (for the mediator, for example, cholesterol) to the crude excess risk (relative risk minus 1) on cardiovascular deaths. Consistent with this approach for every two risk factors for an outcome, we estimated the fraction of risk that is mediated through the other risk (Web Table 9). For the majority of risk factor-mediators direct estimates of mediation similar to body-mass index mediation through cholesterol were not available in published literature. For physical activity, fruits, vegetables, fibre, whole grains, nuts, transfats, and polyunsaturated fatty acids, we estimated the mediated effect on an outcome by the amount of increase in the outcome which is expected through the effect on the mediator level e.g. change in the fasting plasma glucose level by the increase in physical activity. Using this matrix of parameters carrying every two by two combination of the risk factors, we have computed the aggregated burden of disease for every level including behavioural, environmental/occupational, metabolic risks, and finally, all risk factors using the following formula:

$$PAF_{Joasct} = 1 - \prod_{j=1}^{J} \left(1 - PAF_{joasct} \prod_{i=1}^{J} (1 - MF_{jio})\right) equ. 5$$

Where J is a set of risk factors for aggregation, PAF_{joasct} is the population attributable fraction for risk factor i, MF_{jio} is mediation factor for risk factor i mediated through j, cause o, age-group a and sex s, country c and time t. For example the mediation factor of high body-mass index through cholesterol for ischemic heart disease is 0.1 (the mediation of each risk factor through itself is assumed to be zero) and

the mediation factor is 1 when the whole effect is mediated through the mediator such as salt and systolic blood pressure on ischemic heart disease.

We have included childhood wasting and stunting in the risk factors list so that that the joint burden of childhood undernutrition using all three anthropometric indicators (underweight, stunting, and wasting) can be estimated. However, significant covariance observed among these indicators in the population poses a challenge to the assumption of independence used in joint PAF estimation for different risk clusters. Published relative risks for wasting, stunting and underweight do not control for each other. We adjusted the published confounded relative risks for each indicator for the effect of the other two anthropometric indicators⁴³ by simulating the joint distribution of the pooled cohort using variance covariance matrix generated by calculating the mean, variance, and correlation coefficients of height-forage, weight-for-age, and weight-for-height z-scores using Demographic and Health Survey micro-data. Using the adjusted relative risks for all three anthropometric indicators, we have calculated the joint PAF for all three indicators assuming they were independent.

Estimating the overlap between behavioural, environmental/occupational and metabolic risk factors

To avoid double counting in the presentation of overall results, we computed the overlap by estimating seven joint risk distributions using the mediation matrix described above: behavioural risks alone, environmental/occupational risks alone, metabolic risks alone, behavioural and environmental/occupational risks together, behavioural and metabolic risks together, environmental/occupational and metabolic risks together, and all three groups together. The seven quantities were then used to solve for the full set of overlaps between the three sets of risks which can be represented graphically.

Risk factor aggregation and challenges of mediation

In GBD 2010 we estimated the burden of 67 risk factors and selected risk factor clusters. For GBD 2013 we have systematically calculated the burden at all levels in the hierarchy. The rationale for this change and challenges in doing so are presented here.

Background and Rationale for Change

Risk factors are categorized at different levels, so there is a need to aggregate their effects at each level for a better understanding of the contribution of different combinations of risk factors to disease burden. For example, we present the aggregate burden of all dietary risks, in addition to each individual dietary risk. In addition to presenting burden at each level, policy-makers have expressed interest in knowing the total amount of burden that can be attributable to at least one risk factor. For example, being able to show the fraction of each disease that can be attributed to a risk factor helps us identify diseases and injuries for which we have little knowledge about risk factors. All risk factors attributable burden showed that the concentration of evidence is on cardiovascular outcomes and cancers. The aggregation of risk factors is also an essential step in the development of forecasting methods where we know the drivers of risk factors, but little is known about the unexplained disease fractions. National policy-makers in the United Kingdom, China, and elsewhere have continuously expressed interest in this to scope the potential for health gain from preventive interventions that address multiple risk factors.

In GBD 2010 we only aggregated the burden of risk factors for some clusters of risks including access to improved water and sanitation, child and maternal malnutrition, tobacco smoking, alcohol use, dietary risk factors, occupational risk factors, and sexual abuse and violence. We did not aggregate air pollution and metabolic risk factors. In GBD 2013, we aggregated all risk factors into three large categories: behavioral, environmental/occupational, and metabolic risks -- as well as aggregating all GBD risk factors into a single attributable fraction for each diseases and eventually for all-causes of burden.

Aggregating risk factors at different levels share three essential challenges:

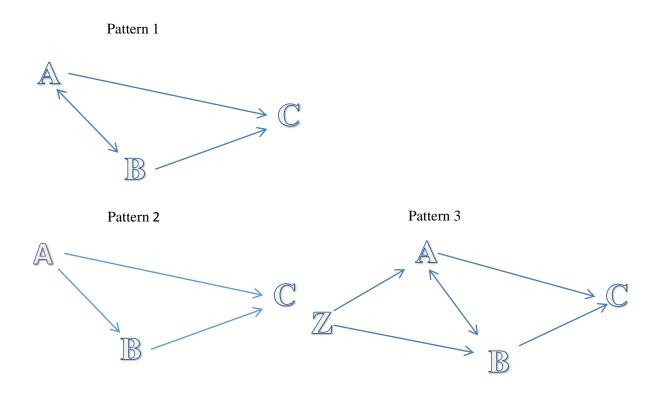

- 1. Risk factor coexistence or aggregation: for example, metabolic risk factors often occur together or high-risk behaviors are related such as drug abuse and unsafe sex.
- 2. Mediation: a risk factor may effect another risk factor that lies in the physiological pathway to a disease outcome. It can be inside a cluster of risk factors such as the effect of obesity through an increase in fasting plasma glucose (FPG) and later cardiovascular disease outcomes, or between clusters of risk factors such as the effect of fiber on cholesterol.
- 3. The formula to calculate the aggregated PAF.

The aggregation method is conceptually applicable to other aggregations such as socioeconomic factors, education, homelessness and refugee status that are being considered for inclusion in future GBD iterations. In the next section, we explain our approach to deal with these challenges.

There are three patterns of associations between risk factors to take into consideration. The first concerns confounding; risk B affects risk A and outcome C (Pattern 1 in Web Figure 1). In these cases the relative risk (RR) for A should be adjusted for B, for example the fruit RR is adjusted for smoking. If part of the effect of A is through B, a mediator, we do not adjust the effect of A for B. For example, we do not adjust the RR of body mass index (BMI) for cholesterol as cholesterol lies in the biological pathway between BMI and cardiovascular outcomes (Pattern 2 in Web Figure 1). The third pattern occurs when risks A and B are proxies of a third variable Z and aggregation aims to estimate the total effect of a latent variable Z,

on C. An example is childhood undernutrition, which is measured by stunting, wasting, and underweight as proxies.

Web Figure 1. Patterns of associations between risk factors

Calculating burden of multiple risk factors

Validation studies have reported congruency between the true risk associated with multiple risk factors affecting the same outcome and a multiplicative aggregation of the population attributable fractions of the individual risk factors (formula below).⁷³

$$PAF_{1..i} = 1 - \prod_{i=1}^{n} (1 - PAF_i)$$
 equ. 7

Where PAF is the population attributable fraction and i is each individual risk factor. The same validation studies also found that the overestimation from ignoring the covariance between risk factors is small. This was important to note as there are few data sources from which we can draw information on covariance.

We endeavored to evaluate RRs that were controlled for confounders. However, as we had to rely on the literature for many RRs we did not always have full control over the choice of confounders controlled for in each study.

Adjusting for mediation

When aggregating the effects of multiple risk factors, we included a mediation factor if a part of the effect of one risk factor was included in the effect estimated for in the mediator. First we prepared a list of possible mediations especially between metabolic risk factors and other risk factors. We found limited data primarily for these categories. We did not assume any mediation effect between risk factors for cancers except for sugar sweetened beverages and BMI.

Danaei and colleagues assumed that part of the effect of BMI on ischemic heart disease (IHD) is through high systolic blood pressure (SBP), cholesterol and FPG.²⁵ The proportion of the BMI effect that can be explained by other metabolic risk factors is the amount of mediation. The difference between the crude RR of BMI on IHD with the RR adjusted for SBP, FPG, and cholesterol reflects the amount of BMI effect on IHD that is mediated and already included in SBP, FPG, and cholesterol:

$$MF = \frac{RR_{crude} - RR_{adjusted}}{RR_{crude} - 1}$$
 equ. 8

We used this approach for estimating mediation factors to adjust PAFs before aggregation.

$$MF = \frac{R_c^+ - R_a^+}{R_c^+ - R_c^-}$$
 equ. 9

So:
$$R_a^+ = R_c^+ - MF * (R_c^+ - R_c^-)$$

$$PAF_{c} = \frac{p*(R_{c}^{+} - R_{c}^{-})}{p*R_{c}^{+} + (1-p)*R_{c}^{-}} = \frac{p*(R_{c}^{+} - R_{c}^{-})}{R_{T}}$$
 equ. 10

If R_c^+ : crude risk of outcome in exposed population

 R_c^- : crude risk of outcome in non-exposed population

 R_a^+ : adjusted risk of outcome in exposed population

 R_a^- : adjusted risk of outcome in non-exposed population

 R_T is the overall rate of the outcome in the population. Since we are interested in the part which is from BMI but through cholesterol, the total risk in the population will be the same for the adjusted RR, so the unmediated part of the risk factor would be:

$$PAF_{a} = \frac{p*(R_{a}^{+} - R_{a}^{-})}{R_{T}} = \frac{p*(R_{c}^{+} - MF*(R_{c}^{+} - R_{c}^{-}) - R_{c}^{-})}{R_{T}} = \frac{p*(R_{c}^{+} - R_{c}^{-})*(1 - MF)}{R_{T}} = PAF_{c} * (1 - MF) \quad equ. 11$$

So for aggregating the PAF of multiple risk factors, we first calculated the part of the effect of every risk factor that is not mediated and then aggregated these assuming they are independent.

Therefore the aggregated PAF would be:

If MF is mediation factor of R2 through R1:

$$PAF_{1,2} = 1 - (1 - PAF_1) * (1 - PAF_2 * (1 - MF_{2/1}))$$
 equ. 12

and a generalization for multiple pathways of R1 through other RFs:

$$PAF_{1..i} = 1 - \prod_{i=1}^{n} \left(1 - PAF_i * \left(1 - \prod_{j=1}^{n} (1 - MF_{i/j}) \right) \right)$$
 equ. 13

For every risk factor outcome pair, the matrix of possible mediations was calculated and used. In the example the matrix of mediation when we aggregate BMI, cholesterol, FPG, and SBP would be:

Web Table 2. Example mediation matrix for BMI, cholesterol, FPG, and SBP

	BMI	Cholesterol	FPG	SBP
BMI	0	0.111	0.148	0.296
Cholesterol	0	0	0	0
FPG	0	0	0	0
SBP	0	0	0	0

Calculating mediation factor

1 – Comparing crude RR versus mediator-adjusted RR

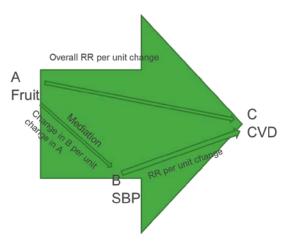

The best example is the mediation of BMI through SBP, FPG, and cholesterol reported by Danaei et al.²⁵ In their meta-analysis, they report the adjusted and unadjusted RR of BMI on IHD and stroke based on combined data from individual cohorts. They calculated the mediation factor using equation 4 and we used it directly as mediation factor in risk factor aggregation.

For some risk factor aggregations we just simply added PAFs. For example, the total burden of smoking including smoking and secondhand smoke is the sum of the estimates of the individual risks because we estimate the burden of secondhand smoke in non-smokers only.

2 – Estimating the mediation factor by pathway of the effect

For many other risk factors there are no data available to use the first method. Instead, we searched studies to estimate the effect of the risk factor (for example fruit) on the mediator (SBP) and finally the expected increase in IHD risk. We pooled available studies to calculate the unit increase in the mediator per unit increase in the risk factor to calculate the size of the IHD RR.

Web Figure 2. Example of pathway between fruit, high systolic blood pressure, and cardiovascular diseases

We have RRs for the effect of A on C and B on C in GBD from a meta-analysis of studies in the literature. The effect of A on B was estimated by analysis of diet trials.

$$RR_{ABC} = RR_{BC}^{\Delta_{AB}}$$
 equ. 14

 RR_{ABC} is expected effect of A through B on C

 RR_{BC} is relative risk of each unit increase in mediator on outcome C

 Δ_{AB} is change in mediator level B per each unit change in A

If RR_{AB} is the overall effect of A on B? then:

The mediation factor would be

$$MF = \frac{RR_{ABC} - 1}{RR_{AR} - 1}$$
 equ. 15

We kept uncertainty of each parameter by generating and following 1,000 draws of the estimates to calculate 1,000 draws of the posterior distribution of the mediation factor. We did not include risk-mediator pairs if the mediation factor was not significant at 5% level (more than 50 out of 1,000 draws were negative). We truncated the mediation factor distribution at 1 where the whole effect of the risk factor on the outcome would be assumed to be through the mediator pathway.

Some mediation factors equal 1 where the whole effect was calculated through other risk factor e.g. the effect of sugar-sweetened beverages through BMI or salt through SBP or when we assumed other risk factors are sources of the exposure, for example fiber is provided by consuming fruit, vegetable, and whole grains.

Dietary risk factors

We searched for diet trials that reported change in SBP, cholesterol, and FPG by change in dietary risk factors, for example fruit and vegetables. We did a systematic search to find clinical trials that reported the baseline values or change in diet levels. We also searched for a list of important hypothetical mediations primarily through metabolic risk factors because of the great burden of metabolic risk factors and a need to aggregate and control for double-counting of the burden, especially for cardiovascular diseases (CVD).

Considering that outcome of metabolic changes such as SBP and cholesterol are measured objectively (compared with subjective measurements that might be affected by patient or physician knowledge about the intervention group),), and there are no issues with blinding and analytical concerns like type of analysis (intention-to-treat or per-protocol), we think they provide a sufficient data on the short-term effect of diet on metabolic risk factors.

Long-term effects are more difficult to capture, given that there is little data available on long-term effects in the literature. Future analysis of cohort studies will be necessary to understand the long-term effects of diet on metabolic risk factors.

We modeled change in a given mediator (e.g. cholesterol) per unit change in diet components. The best possible approach would be controlling for other dietary changes, but it is not possible because of few data points and uncertainty levels for both diet and metabolic risk change. With a limited number of studies providing data points for the analysis and no access to micro-data from diet trials, it is not possible to control for other diet components.

In cases in which there were very few data points, such as for unsaturated fatty acids and trans fats, or if we could not find trials, mediations were excluded.. Also, BMI was excluded because our diet analyses are adjusted for a 2,000 calorie diet, thereby addressing mediation through BMI and obesity.

We did not include possible mediation/interaction of diet with many other risk factors and outcomes besides metabolic risks. Fruit and vegetables could have interaction with smoking and possibly air pollution on cancers, but we did not identify sufficient evidence for such an analysis. We assumed all effects of fiber are captured in fruit, vegetables, whole grain and nuts and seeds, so we assumed complete mediation.

In the case of fibre, the mediation is counted as one mechanism of producing covariance between risk factors, and the calculation depends on the concept and direction of mediation. To be consistent with the methodology employed in the GBD, we must aggregate and avoid double-counting of burden and we should control covariance. Covariance might be with or without interaction and mediation is one way of subsequent double-counting of the burden. We think that through mediation analysis we are able to quantify non-random and biologically plausible covariance and improve risk factor aggregation.

Physical activity

We found cohort studies on the effect of physical activity on FPG. The data was more on the effect of physical activity on diabetes incidence, so we calculated the shift in FPG using the provided RR value. We used this to calculate the mediated part of effect of physical activity on CVD.^{74–80}

Air pollution

We looked for cohort and time series studies but the data were limited. We found only one study with the effect of last year average of particle pollution (PM) 2.5 on SBP, FPG and cholesterol.⁸¹ However, the effects through FPG and cholesterol were bigger than the effect expected for that level of PM2.5, indicating significant overestimation of the mediation. We found time series studies with different PM2.5 lag (by day) that show very short-term and confounded effects. So we decided to add this when stronger evidence is available.

Assumed mediations

For the risk factors with PAFs of 100% such as FPG and diabetes, low estimated glomerular filtration rate and chronic kidney disease, hypertension and hypertensive heart disease, alcohol and alcohol disorders, childhood underweight and protein-energy malnutrition, and childhood wasting and protein-energy malnutrition, and drug use and drug use disorders, no mediation is needed.

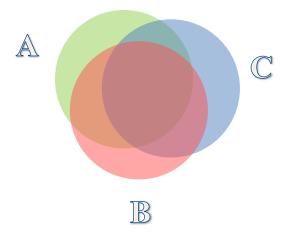

3 – Piecewise aggregation (Pattern 3)

There are three anthropometric indicators that are highly correlated: childhood underweight, stunting, and wasting, as demonstrated in Web Figure 3. Available RRs for each indicator are not adjusted for the other two because there is a high correlation between these indicators and also interaction where the majority of the burden occurs. Estimating the total burden due to undernutrition, a latent variable, is difficult. The three anthropometric indicators are not independent, so the covariance between them should be considered. This was the main reason that GBD 2010 only included childhood underweight. If covariance between these indicators is significant (as is shown in Web Figure 3), aggregating these indicators assuming independence would overestimate the total burden significantly.

To use the best available data, we adjusted observed RRs reported by Olofin et al for underweight, stunting and wasting by simulating the joint distribution of the three indicators using the distribution of each indicator and covariance between indicators in the countries included in the meta-analysis (extracted from Demographic and Health Survey (DHS) micro-data). Based on the analysis done by McDonald et al, we assumed there is an interaction between the three indicators, and extracted the interaction terms from the corresponding analysis. We calculated the adjusted RRs by minimizing the error between observed crude RRs (from meta-analysis) and expected crude RRs derived from adjusted RRs. To use the

best available data, we adjusted observed RRs reported by Olofin et al for underweight, stunting and wasting by simulating the joint distribution of the three indicators using the distribution of each indicator and covariance between indicators in the countries included in the meta-analysis (extracted from Demographic and Health Survey (DHS) micro-data). Based on the analysis done by McDonald et al, we assumed there is an interaction between the three indicators, and extracted the interaction terms from the corresponding analysis. We calculated the adjusted RRs by minimizing the error between observed crude RRs (from meta-analysis) and expected crude RRs from adjusted RRs, interaction terms, and joint distribution of the risk factors.

Web Figure 3. Venn diagram demonstrating the correlation between childhood underweight, stunting, and wasting

After adjusting for the three risk factors, we calculated the PAFs and aggregated underweight, stunting and wasting burden (equation 4).

Uncertainty of aggregated and mediated PAFs

We generated 1000 draws of posterior distribution of mediation factor calculated by different methods to use beside draws of other inputs to the PAF aggregation.

Important assumptions in aggregating risk factors and including mediation

- 1 The mediation factors or PAF adjustments are similar across countries, age, sex, and years. While it is quite likely that the size of mediation is different in different populations, there is little data to inform the covariance between different risk factors or the mediation factor amount by age and countries. For example in some countries, the size of the mediated BMI-IHD PAF through cholesterol, calculated by the mediation factor, was even bigger than the total burden of cholesterol, indicating that less effect of BMI is mediated through cholesterol and mediation factors are not similar across countries.
- 2 For many risk-mediator-outcome pairs, there are no data available, so we assumed the mediation is zero.
- 3 Since the covariance between undernutrition indicators is different by countries (and across time, results were not reported), and there is an interaction between these indicators, the total burden might be underestimated.

4 – It is assumed that there is no significant covariance between PAFs, which might not be true between some risk factors such as between metabolic risk factors. While this overestimation is controlled by using adjusted RRs, using crude RRs for BMI and other metabolic risk factors may cause significant overestimation of aggregated metabolic risks burden.

Appendix B: Risk Factor Modeling Strategies

Environmental and occupational risks

Unsafe water, sanitation, and handwashing

For GBD 2013, we changed the definition of exposure, updated relative risks based on recently published meta-analyses to match new exposure definitions, and redefined the TMREL to estimate the burden of unsafe water and sanitation. The inclusion of handwashing as a new risk factor was another major change since GBD 2010. Due to changes in exposure definitions, as expected, GBD estimates of burden attributable to both unsafe water and sanitation are higher in 2013 compared to 2010. The addition of a whole new risk factor, handwashing, to the cluster has also led to higher estimates of attributable burden to the overall category of unsafe water, sanitation, and handwashing.

The GBD 2013 definition of unsafe water incorporates access to improved water facilities as well as household use of different water treatment techniques to improve water quality. Similarly, exposure to unsafe sanitation is defined by household access to sanitation facilities but includes the addition of a third category of exposure which is improved sanitation connected to sewer system to define minimum risk of exposure. Finally, exposure to unsafe handwashing was defined by lack of handwashing with soap and water after using a toilet or after contact with excreta (including children's excreta). Household level exposure defined by access to water and sanitation facilities were extracted from household surveys. Data on self-reported practice of point-of-use household water treatment and proportion of observed handwashing stations were also extracted from surveys and published literature when available. Exposure was modeled using a three-step modeling process which includes ST-GPR.

Relative risks corresponding to the newly defined exposure categories for unsafe water were calculated by assuming that the combined effect of water treatment and access to water facilities is multiplicative. Relative risks for unsafe sanitation and handwashing were updated based on newly published meta-regressions. 12, 13

The TMREL for unsafe water changed from all households using an improved water source to all households having access to piped water supply and also filtering or boiling their water before drinking. For unsafe sanitation, the TMREL changed from all households using an improved toilet facility to all households having access to sewer connection. Finally, the TMREL for handwashing was defined as all households practicing handwashing with soap and water after using a toilet or after contact with excreta (including children's excreta).

PAFs were calculated using the equation for polytomous risks outlined in the Methods section of the Web Appendix.

Ambient particulate matter pollution and ambient ozone pollution

Exposure is drawn from estimates of annual concentration of PM2.5 – generated by combining data from atmospheric chemistry transport models and satellite observations of aerosols in the atmosphere. Modeled concentrations are then calibrated against observations from ground-level monitoring of particulates in more than 75 countries. This calibration is done by spatially matching the gold-standard ground data to the corresponding data from transport and satellite modelling. After controlling for measures of data quality in the ground monitor data, the resulting relationship is quantified and used to predict ground monitor data globally. The ground-level data is a source of major change since GBD 2010 as it has been augmented via literature review, web scraping, and contact with experts worldwide.

Relative risks are generated using integrated exposure curves that are fit to available epidemiological data using a Bayesian Markov Chain Monte Carlo (MCMC) approach and a modified power function. The integrated exposure curves are estimated based on published relative risks for ambient air pollution, household air pollution, secondhand smoking, and active smoking exposure. The concentration of particulate matter for each type of exposure is estimated based on literature values and used to map the relative risks to a curve generated for the entire range of exposure values. One slight deviation from GBD 2010 was that studies were added for adult pneumonia from active smoking cohort studies, leading to the addition of this cause-outcome pair being reflected in final burden estimates for all types of particulate matter exposure.

The relative risks are generated on the grid-level based on estimated exposure, and then applied to generate PAFs. These PAFs are aggregated by population to create national-level estimates of attributable burden. One final change to the process is a slight modification to the TMREL, which comes from the minimum and 5% concentration of particulate matter in an aggregate of cohort studies. Several studies were deemed to no longer fit the inclusion criteria and were removed from the analysis...

Household air pollution

The methodology used to estimate the burden of household air pollution from solid fuels has remained largely unchanged since GBD 2010. The major change in methodology compared to 2010 was in the exposure modeling step where we opted to use a three-step ST-GPR strategy instead of a mixed-effect linear model to generate the time series for all country years included in the analysis.

Exposure to household air pollution was defined as the proportion of households using solid cooking fuels. Data on household use of solid fuels were extracted from nationally representative household surveys. Fuels such as coal, wood, charcoal, dung, and agricultural residues are classified as solid fuels in our analysis. Primarily, data sources included in the exposure database were population representative surveys such as DHS, Multiple Indicator Cluster Survey (MICS), Living Standards Measurement Study (LSMS), national censuses etc. Additional country-specific data sources have also been added for subnational provinces in China and federal states in Mexico. Exposure was modeled using a three-step ST-GPR process.

Relative risks were extracted and applied for IHD, CVD, lower respiratory infections (LRI), lung cancer, chronic obstructive pulmonary disease (COPD), and cataracts. Similar to GBD 2010, the relative risks applied to cataract, COPD, and lung cancer were determined using direct epidemiological evidence. These relative risks were updated using estimates from newly published meta-analyses (Smith et al 2014).⁸⁴

When direct evidence was not available for outcomes like IHD, CVD and LRI, we used risk ratios generated from integrated exposure curves. The integrated exposure curves were rerun with the addition of updated meta-regressions and newly available studies. Relative risks were then re-extracted from newly generated exposure curves. To utilize evidence from integrated exposure curves, PM 2.5 mapping values were generated for all country-years using a meta-analysis of published studies that measured PM 2.5 levels associated with household use of solid cooking fuels.

PAFs were calculated using the equation for polytomous risks outlined elsewhere in the methods section of the Web Appendix.

Residential radon

There has been moderate change to the methodology to estimate radon exposure. New data were added and the modelling process was updated by shifting it from a nested random effects model to ST-GPR.

Radon exposure is determined using values curated by an expert group. These values are taken from a variety of sources including literature, government agencies, and monitoring stations. Their methodology is then inspected to determine if they are robust enough to be considered the country-level averages. This dataset was updated for GBD 2013 by adding new data points. The database is then modeled using ST-GPR to generate estimates for all country years. Previously, a simple nested random effect models was used to create these predictions. The RR and TMREL are both taken from literature values that were not updated for GBD 2013.

Lead exposure

There has been significant change to the methodology to estimate lead exposure. A literature review was conducted to update the exposure dataset, to include new studies and those missed by previous reviews. Global exposure was previously modelled using age-integrating Bayesian hierarchal modelling (DisMod-MR). The modelling process was updated for GBD 2013 by shifting to ST-GPR methodology. This allowed for estimates of all country-age-sex-year groups for single years instead of five year periods. This approach improved the granularity of estimates for bone lead, which requires back-estimation of previous blood lead to calculate a cumulative blood lead index.

Exposure to lead is determined using values extracted from literature regarding blood lead. The blood lead database for GBD 2010 was augmented with an updated literature review for the years 2008-2013. This combined approach yielded 1,573 usable data points from 332 different studies, which spanned the years 1964 to 2013. More than 400 new data points were added, including 337 for children and 102 country-years. The update for children is particularly relevant since blood lead impacts child IQ. The database of literature values was modelled for data-sparse countries using ST-GPR. These values were used as blood lead exposure. The second pathway of burden is related to bone lead exposure, which was estimated by calculating a cumulative blood lead index for cohorts using estimated blood lead over their lifetime. The cumulative blood lead index is then used to estimate bone lead using a scalar defined by the literature.

The TMREL is taken from literature estimates of pre-industrial blood lead in humans. The blood lead relative risks were taken from a 2005 pooled analysis that was updated for GBD 2010. The bone lead relative risks were taken from a 2008 meta-analysis that was updated for GBD 2010. Neither of these effect sizes were modified for GBD 2013.

Occupational risks

Methods used to estimate the burden of occupational risks has remained largely unchanged except for occupational injuries and asbestos. For occupational injuries, the major change in methodology compared to GBD 2010 was in modeling rates of fatal injuries which are used to calculate PAFs directly. In GBD 2010, these rates were modeled by three broad groups of industries: agriculture, manufacturing, and service. However, for GBD 2013, injury rates have been modeled by the most detailed level of industry provided by the International Labor Association (ILO) fatal injury database. Furthermore, instead of using a three-step modeling strategy using ST-GPR, the strategy for this round was to use a linear mixed effects model to estimate rates of injury by industry type with nested random effects by region and country. Compared to GBD 2010 where burden of all unintentional injury outcomes were attributed to all industries, in this round of GBD, burden attribution by industry was done for a custom set of injuries that

have been selected for each industry a priori based on expert group consultation. This change in methodology led to lower estimates of overall burden of occupational injuries in GBD 2013 compared to 2010.

The method used to estimate the burden of asbestos is different compared to all other carcinogens. We use the Peto-Lopez method to estimate the cumulative exposure to asbestos using data on mesothelioma deaths in a smoking impact ratio analogue. While the same methodology was used in GBD 2010, the input of mesothelioma deaths in the general population by country, age, and sex is different as it is now modeled using ensemble modeling after its addition to the list of causes analyzed for GBD 2013.

In the absence of direct measures of exposure to occupational risk factors, except for occupational asbestos, we estimated exposures for most of these risks by using data on the composition of a country's workforce by industries or occupations or by relying on rate of injuries for each industry over time. This data was obtained from the ILO database which are derived from censuses, national labor forces surveys, insurance records, and administrative records. For 2013, we updated our exposure models by using the newly downloaded datasets from the ILO database for all occupational risks. Relative risks were updated where newly published studies were available. Trichloroethylene was added to the list of occupational carcinogens to be consistent with published evidence (Kelsh et al 2010). 85 The published meta-analysis shows a causal association between occupational exposure to trichloroethylene and kidney cancer.

PAFs were calculated using the equation for polytomous risks outlined in the methods section of the Web Appendix for all occupational risks except for occupational injuries.

Behavioral risks

Suboptimal breastfeeding

Methods used to estimate the burden of suboptimal breastfeeding in 2013 has undergone limited changes since GBD 2010. A substantial portion of the update in the exposure model involved adding new data sources that are primarily nationally representative household survey data. Relative risks and TMREL used in the analysis have also remained the same. The only other notable change in the exposure modeling step was the choice of modeling exclusive, predominant, and partial breastfeeding as proportions of any breastfeeding to ensure that the sum of these three types of feeding in children under the age of 6 months do not exceed the envelope of all children receiving some breastfeeding in the same age group.

Exposure data sources are largely population representative survey series such as DHS, MICS, LSMS, and other national nutrition surveys. Additional data sources have also been added for subnational locations for China and Mexico. Data on exclusive, partial, predominant, and any breastfeeding were extracted for children under the age of 6 months from nationally representative household surveys. Similarly, data on continued breastfeeding was extracted from survey for children of age 6-23 months. Exposure was modeled using a three-step modeling process which includes ST-GPR.

Relative risks for LRI were updated based on the publication of a new meta-analysis assessing the risk of suboptimal breastfeeding (Lamberti et al 2013).⁴ Given the lack of sufficient evidence to determine a causal association between suboptimal breastfeeding and enteric fevers, we excluded typhoid and paratyphoid fevers from the list of outcomes paired with both non-exclusive and discontinued breastfeeding previously. This was done after consultation with expert groups who helped assess the strength of evidence regarding the causal relationship between all risk factors associated with typhoid and paratyphoid fevers.

PAFs were calculated using the equation for polytomous risks outlined in the methods section of the Web Appendix.

Childhood underweight, wasting, and stunting

Compared to GBD 2010 there has been little change in the methodology used to estimate exposure of childhood underweight. However, childhood wasting, and stunting are new additions to the risk factors list for GBD 2013. The burden attributable to childhood stunting and childhood wasting were assessed but not reported in GBD 2010. As a result, although they are included as new risks the methodology used to estimate exposure to both childhood stunting and wasting has remained unchanged and is similar to that of childhood underweight.

One major update in the exposure model for all three risks (underweight, stunting, and wasting) involved adding new data sources which are largely nationally representative household surveys. Additional data sources have also been included for subnational provinces in China and states in Mexico. Exposure data was extracted from household surveys such as DHS, MICS, nutrition surveys, and other survey with child anthropometry data. First, we modeled the prevalence of children aged 0-59 months who fall below 2SDs of the median weight-for-age, height-for-age, or weight-for-height growth curves of the 2006 World Health Organization (WHO) reference population. This was modeled using a three-step modeling process which includes ST-GPR.

The risk of childhood underweight, stunting, and wasting depend on the severity level of undernutrition. To generate exposure estimates for varying levels of severity we used input data and performed a linear regression of the logit-transformed prevalence of malnutrition in all three severity levels against the logit-transformed prevalence of underweight, stunting, and wasting below -2SD. This model was then used to predict the fraction of children under the age of 5 who fall in each of the severity categories for all three childhood under nutrition risks (underweight, stunting, and wasting).

Relative risks for all three childhood undernutrition risks were updated based on a newly published study that conducted a pooled cohort analysis (Olofin et al).⁸² Malaria and enteric fevers are no longer included in the list of outcomes paired with childhood underweight, stunting, and wasting given the lack of sufficient evidence to determine a causal association.

For GBD 2010, we assumed a TMREL based on the WHO 2006 growth standard. For GBD 2013, the TMRELs for underweight, stunting, and wasting where all children under the age of 5 are above -1SD of the WHO 2006 standard weight-for-age, height-for-age, and weight-for-height curves respectively.

PAFs for all three childhood under nutrition risks were calculated using the same formula used for all polytomous risks in GBD 2010.

Iron deficiency

Please see "Global, regional, and national incidence, prevalence, and YLDs for 301 acute and chronic diseases and injuries for 188 countries, 1990-2013: a systematic analysis for the Global Burden of Disease Study 2013" for a detailed description of the estimation process and data sources (Vos et. al, 2015).⁵

Vitamin A deficiency

The modeling strategy to estimate vitamin A deficiency exposure is similar to that of the GBD 2010. We obtained data from the WHO database on vitamin A deficiency and added new data from the literature, the expert group and three demographic and health surveys. The data were modeled in DisMod-MR 2.0 with a study level covariate indicating whether the data were at the national or subnational level, and two

country level covariates (i.e., malnutrition proportion and vitamin A supplementation coverage). Vitamin A supplementation coverage is a newly added covariate to take into account the vitamin A supplementation interventions. The meta-analysis for the relative risk was also updated by including two new studies. 86,87

Zinc deficiency

Some methodological changes have been made in GBD 2013 to estimate childhood zinc deficiency. Estimates were previously taken from literature and then modelled using a mixed effects model. Through consultation with the expert group, the method is now conducted at IHME and has been updated with new Food and Agriculture Organization (FAO) data and a more advanced equation to predict zinc absorption based on estimated diet components. The meta-analysis for the relative risk was also updated by the inclusion of two new studies.

Exposure to zinc deficiency is estimated using the United Nations (UN) FAO Food Balance Sheets. These sheets present data on the amount of kilocalories available for human consumption of 95 different food commodities. Using a composite index generated by the expert group, it was possible to estimate the amount of zinc and phytate in the average diet at the country level. Phytate is a substance in food that limits zinc absorption. Using an equation defined by literature, the average total absorbed zinc was estimated based on the ratio of zinc to phytate in a country diet. An assumption of normal distribution with an SD of .25 is then used to estimate the percent of the population that would fall below the recommended zinc intake. The RR is defined from clinical trials after adjustment for background zinc estimates that come directly from the GBD process. The TMREL is no zinc deficiency and was not updated for GBD 2013.

Smoking

For modelling burden attributable to tobacco smoking, we used the smoking impact ratio (SIR) developed by Peto and colleagues for cancers, chronic respiratory disease, pneumonia and interstitial lung disease. The SIR can be defined as the population lung-cancer mortality in excess of never-smokers, relative to excess lung-cancer mortality in a known reference group of smokers. This is then adjusted to account for differences in the baseline never-smoker lung-cancer mortality rates across populations.

In GBD 2010, we used the American Cancer Society Cancer Prevention Study, Phase II (CPS-II) for the reference population for all countries except China, Japan, Korea, Singapore, and Brunei Darussalam. For these countries, never-smoker lung-cancer mortality rates came from 13 large Asian cohort studies. In GBD 2013, we expanded the countries for which we applied different non-smoker lung cancer mortality rates to include all countries in the Asia-Pacific high-income, East Asia, South Asia, and Southeast Asia regions.

Relative risks for SIR and disease outcomes were updated to reflect Kontis et al (2014) re-analysis of CPS-II smokers using Cox proportional hazard models.⁸⁸

In GBD 2013, we used 5-year lagged smoking prevalence for all CVD outcomes, TB, diabetes and asthma, for which tobacco exposure has more short-term effects. This was changed from a 10-year lagged smoking prevalence, which was used in GBD 2010. The adjustment in lag time is informed by literature that demonstrates the much shorter impact of smoking on development of these disease outcomes, and conversely, the fast-acting risk reduction accompanied by quitting smoking (Unal et al 2003).⁸⁹

Secondhand smoke

The estimation strategy for burden attributable to secondhand smoke (SHS) was updated for both exposure and relative risk. Exposure to secondhand smoke was modeled in DisMod-MR 2.0 for GBD 2013, whereas it was modeled using ST-GPR for GBD 2010. Exposure levels reflect prevalence of tobacco smoke inside the home among non-smokers (ex-smokers and occasional smokers were considered non-smokers). Study-level fixed effects were used to adjust data points with the following alternative case definitions: exposure to secondhand smoke exposure at home and/or work (rather than exposure inside the home only), living with a smoker (i.e. study asked respondent whether their spouse smokes or their parent(s) smoke), or if the prevalence figure includes exposure to tobacco smoke outdoors as well as indoors).

Country-specific relative risks are generated using integrated exposure curves that are fit to available epidemiological data using a Bayesian MCMC approach and a modified power function. The integrated exposure curves are estimated based on published relative risks for exposure to ambient air pollution, household air pollution and secondhand tobacco smoke, as well as active smoking. The concentration of particulate matter for each type of exposure is estimated based on literature values and used to map the relative risks to a curve generated for the entire range of exposure.

GBD 2013 SHS PAF estimates for 1990 are similar to GBD 2010 estimates, but PAF estimates for 2010 are lower in this round of GBD than GBD 2010 PAF estimates. This is because a much larger body of data sources were added, especially for recent years, in addition to a global trend toward smoking outside the home.

Alcohol use

As stated in the main text, we have updated our alcohol per-capita estimates using ST-GPR and DisMod-MR 2.0 to map survey data onto country-level consumption data. Furthermore, we developed new estimates for current drinkers, lifetime abstainers, former drinkers, binge drinkers and binge times by tabulating survey information from available nationally representative sources (or subnationally representative when appropriate) and then using the results to inform DisMod-MR 2.0 models. Through DisMod-MR 2.0, we produce estimates for every GBD age, sex, year, and country combination. For the three mutually exclusive categories (abstainers, former drinkers, current drinkers), the results were squeezed so that the three proportions would sum up to one. This is required because each model was processed independently (e.g. we could not enforce a ceiling of summation to one between the three models) as well as differing information levels/quality between the categories. Binge drinkers (the proportion of drinkers that have had a binge event in the last year) and binge times (proportion of days that a binger has a binge event) were calculated in a similar way (e.g. survey tabulation and DisMod-MR) but were not squeezed as these are independent of the other categories. A binge event is defined as consuming 48 grams of alcohol in a single occasion for females and 60 grams of alcohol in a single occasion for males.

Additional changes not listed in the main text include updates to the relative risks and PAF modeling procedure for ischemic stroke and ischemic heart disease.

We also changed the relative risks and PAF modelling procedures for several causes in Russia, Belarus, and Ukraine. These changes were informed by the results of recent cohort study.⁹⁰

In our injuries modeling, we have discontinued using a scalar to derive the PAF of injury mortality from injury morbidity as the component studies did not meet our revised requirements of representativeness for inclusion in the modeling process. A scalar to derive the female PAF for motor vehicle accidents from the

male PAF was similarly discontinued. These are now calculated separately in concordance with other risk factors.

Drug use

The modeling strategy for injecting drug use exposure did not change, but the methodology for calculating PAFs for the Human Immunodeficiency Virus (HIV), Hepatitis C and Hepatitis B changed substantially.

The proportion of HIV attributable to drug use was modeled in DisMod-MR 2.0 as a proportion of newly diagnosed cases of HIV that were acquired from injecting drugs. This data came from the following sources: UNAIDS, European Centre for Disease Prevention, The Kirby Institute (AUS) and Gouws et al. 2006. The following three broad routes of HIV transmission were modeled in DisMod-MR 2.0: all sexual transmission, injecting drug use and "other" (excluding cases of unknown origin). The model outputs of these three portions are then re-scaled to sum to 100%, and the scaled results for proportion of HIV transmitted by intravenous drug use by country, year, age and sex are used directly as the PAF of HIV due to injecting drug use.

PAFs on Hepatitis B (HBV) and Hepatitis C (HCV) prevalence due to injecting drug use were calculated using a cumulative risk approach, whereby the history of ever injecting drugs, and the accumulated associated risk of incident HCV or HBV due to injecting drug use, relative to the overall risk of HCV or HBV infection at the population level was estimated in birth cohorts for each country from 1960 to 2013. We start accumulating risk in 1960 because we assume there was no injecting drug use prior to this date. This method required a time series of the following from 1960-2013 for each GBD country, year and 5 year age group: prevalence of ever injecting drug use, incidence of acute HCV/HBV, and a pooled absolute risk of HCV/HBV among ever-injecting drug users. The pooled absolute risk for HCV and HBV came from a meta-analysis of longitudinal epidemiological studies that reported a HCV or HBV seroconversion rate among injecting drug users (excluded studies focusing on recent injectors/adolescents or reinfection). The denominator of the PAF was the cumulative overall incidence of HCV/HBV after age 15 (assume no injecting drug use prior to this age). The numerator of the PAF was the cumulative incidence of HCV/HBV attributable to injecting drug use, calculated as the product of the PAF on HCV/HBV incidence and the incidence rate of acute HCV/HBV.

$$\frac{\textit{Cumulative incidence due to IDU}}{\textit{Cumulative incidence overall}} = \frac{1 - \prod_{a=15}^{a=n} (1 - P_{ay} * R)}{1 - \prod_{a=15}^{a=n} (1 - I_{ay})}$$
 equ. 16

Where:

I = annual incidence rate of Hepatitis B or Hepatitis C

a = age (15-84)

y = year (1960-2013)

P = prevalence of ever-injecting drug use

R = pooled absolute risk of Hepatitis C or Hepatitis B among those who have ever used injecting drugs

Dietary risk factors

Exposure data from dietary surveys are used for all dietary risk factors. For milk, nuts and seeds, red meat, seafood omega-3 fatty acids, vegetables, and whole grains, data from the UN FAO food balance sheets were also used as direct model input data, whereas in GBD 2010 FAO data was used in these models as country-level covariates. We additionally updated our method for adjusting dietary sodium data to the level of gold-standard, urinary sodium data for our sodium model. For trans-fatty acids, we updated our method for adjusting industry data on partially hydrogenated vegetable oil to the level of gold-standard dietary survey data for trans-fatty acid consumption.

DisMod-MR 2.0 was used to model patterns of dietary intake for all dietary risk factors. DisMod-MR 2.0 uses a cascade approach which enabled us to estimate consistent values of dietary intakes for multiple levels of location hierarchy (global, super region, region, and country), which are rescaled by local data. There were only two levels of estimation in DisMod-MR 1.0, used in GBD 2010.

A new approach is used to generate uncertainty of DisMod-MR 2.0 draws. The new method models the relationship between standard deviation and mean and uses fixed effects on each dietary risk factor and super-region.

Relative risks were updated for several risk-outcome pairs. New approaches were used to generate relative risks for sodium and sugar-sweetened beverages, which are mediated through systolic blood pressure and BMI, respectively. Diabetes was added as a new outcome for diet low in nuts and seeds and mouth, larynx, and pharynx cancers were removed as outcomes for diet low in vegetables.

TMRELs for dietary risk factors are drawn using a uniform distribution from between upper and lower bounds of optimal intake derived from the literature and national recommendations on consumption for each dietary item.

Childhood sexual abuse

The estimation strategy for burden attributable to childhood sexual abuse did not change substantially, but we produced estimates for 1990 and 1995, which was not done for GBD 2010. In addition, we estimated exposure in DisMod-MR 2.0 separately for males and females, since we observed little correlation between the prevalence of child abuse among females and males, and modeling both sexes together was causing unreasonable estimates in countries where we only had data for one sex. An updated literature review was conducted for publications on prevalence and these results were also incorporated into the exposure models. The associated health outcomes and effect sizes were not changed.

Intimate partner violence

The estimation strategy for burden attributable to intimate partner violence (IPV) did not change substantially, but we produced estimates for 1990 and 1995 in GBD 2013, which was not done for GBD 2010. We also added HIV/AIDS as an outcome in response to bolstered causal evidence from the following two prospective studies:^{92,93}

The pooled relative risk for HIV came from a meta-analysis of these two studies. PAFs on HIV prevalence due to IPV were calculated using a cumulative risk approach whereby the history of exposure to IPV and the accumulated associated risk of incident HIV due to IPV, relative to the overall risk of HIV infection at the population level was estimated in birth cohorts for each country from 1980 (genesis of HIV epidemic) to 2013. This required a time series of the following from 1980-2013 for each GBD country, year and 5 year age group: IPV prevalence, HIV incidence, the proportion of HIV incidence that

is from sexual transmission and not commercial sex work (CSW), and a pooled incidence rate ratio for the risk of incident HIV, given exposure to IPV. The denominator of the PAF was the cumulative overall incidence of HIV after age 15 (assume no IPV exposure prior to this age). The numerator of the PAF was the cumulative incidence of HIV attributable to IPV, calculated as the product of the PAF on HIV incidence and the sexually transmitted/non-CSW HIV incidence rate.

$$\frac{\textit{Cumulative HIV incidence due to IPV}}{\textit{Cumulative HIV incidence overall}} = \frac{1 - \prod_{a=0}^{a=n} (1 - PAF_{ay} * I_{ay})}{1 - \prod_{a=0}^{a=n} (1 - I_{ay})} equ. 17$$

Where:

I = annual incidence rate of HIV a = age (15-84) y = year (1980-2013)

 $PAF_{HIV\ incidence} = \frac{[Prevalence\ of\ IPV]_{ay^*\ (IRR-1)}}{[Prevalence\ of\ IPV]_{ay^*\ (IRR-1)+1}} equ.\ 18$

Unsafe sex

Unsafe sex has been added as a new risk factor for GBD 2013, after difficulty fitting this risk into the exposure/relative risk framework used in GBD 2010. For GBD 2013, we model unsafe sex using a categorical approach to circumvent the challenges of fitting this risk factor into an exposure-relative risk framework and instead directly model population attributable fractions due to unsafe sex for our outcomes of interest.

Unsafe sex is defined in GBD 2013 as the risk of disease due to sexual transmission. The definition of our theoretical minimum is no exposure to a disease agent through sex.

The outcomes associated with unsafe sex that we include are: all sexually transmitted diseases, cervical cancer, and HIV.

For cervical cancer and all sexually transmitted diseases (STD), the fraction attributable to unsafe sex is set to 1.

For HIV, the following approach is used: Data on the proportion of newly diagnosed HIV cases attributed to sexual, injection drug use, and other routes of transmission are extracted from literature sources, primarily UNAIDS Country Progress Reports and governmental epidemiological records. The proportion of HIV attributable to unsafe sex is modeled in DisMod-MR 2.0. The DisMod-MR 2.0 output is prepped and the resulting PAF is directly applied to HIV burden to determine the fraction attributable to unsafe sex.

Low physical activity

The estimation strategy for burden attributable to low physical activity changed considerably for both exposure and relative risk. We used the same activity level categories for GBD 2013 as we did in GBD 2010 (inactive (<600 metabolic equivalent of task (MET)-min/wk), low active (600-3,9999 MET-min/wk), moderately active (4,000-7,999 MET-min/wk), highly active (>=8,000 MET-min/wk)).

However, we changed the "gold standard" case definition from the Global Physical Activity Questionnaire (GPAQ) to the International Physical Activity Questionnaire (IPAQ), due to concern that the GPAQ was not adequately capturing "domestic" housework and yard activity. An empirical

comparison between the World Health Survey (IPAQ) and the WHO Study on Global AGEing and Adult health (SAGE) (GPAQ) showed significantly lower activity levels assessed using GPAQ as compared to IPAQ for females in low income countries. We calculated an adjustment factor to apply to GPAQ surveys for females only (since the difference between questionnaire activity level estimates were not significantly different for men). A regression was fitted to the data from nationally representative surveys that used either GPAQ or IPAQ for each activity category, where the dependent variable was the logit of the proportion in the relevant activity level and the main independent variable was an interaction between super region and survey (1=GPAQ, 0=IPAQ), with fixed effects for age categories and a country level random effect.

We also adjusted non-nationally-representative urban and rural data points. We constructed an urbanicity covariate that is equal to 1 for urban data points, 0 for rural data points and the proportion urban for the country for nationally representative data points. The dependent variable was the logit of the proportion in the relevant activity level and the main independent variable is an interaction between sex and urbanicity, with fixed effects for age categories and a country level random effect.

After crosswalking the activity proportions, we estimated the proportion in each of these four groups using six separate DisMod-MR 2.0 models. We use six models rather than four to accommodate the different MET-minute/week cutoffs presented in tabulated data sources where individual unit record data was not available.

- Model A (inactive) <600 MET-min/week
- Model B (low, moderate or high activity) >= 600 MET-min/week
- Model C (low active) 600- 3999 MET-min/week
- Model D (moderately or highly active) > 4000 MET-min/week
- Model E (moderately active) 4000-7999 MET-min/week
- Model F (highly active) >= 8000 MET-min/week

Since the threshold for inactivity is consistently less than 600 MET-minutes/week, the vast majority of tabulated data was broken down into proportion inactive (model A) and proportion low, moderate or highly active (model B). Since we had the most data for models A and B, we rescaled the sum of the proportion in each category to be equal to one. Next we rescaled the sum of model C and D to be equal to the rescaled value from model B. Then we rescaled the sum of models E and F to be equal to the rescaled value from model D. After these three rescales we were left with a proportion for each of the four categories that all sum to 1.

The health outcomes associated with low physical activity were not changed, but updated relative risks were generated for each health outcome: breast cancer, colon cancer, diabetes, IHD, and stroke. A systematic review of epidemiological literature was conducted for each health outcome, and effect sizes from relevant studies were pooled using Bayesian meta-regressions to generate a continuous risk curve for each outcome. Epidemiological papers were prepped for analysis by Bayesian meta-regression by converting the activity level associated with the relative risk to total marginal MET hours of activity per week. To convert recreational or occupational METs to total marginal METs, log-log ordinary least squares regression was performed on available unit record exposure data that used the GPAQ. Since the GPAQ captures activity in each domain separately, this allowed mapping from domain-specific metrics to total marginal activity. The regression was applied to the MET-minutes/week cutoffs for the activity categories in relative risk papers that reported MET-minutes/week or were converted directly to MET-minutes/week, resulting in estimated total marginal weekly activity for each relative risk level.

When relative risks were reported in the literature based on low, moderate and high activity categories, these were mapped to the physical activity exposure distribution to generate estimates of total marginal activity for each activity level category. To do so, a percentile cutoff was assigned to each activity category reported by a study based on the percentage of the study population falling into that activity category. A percentile value was also assigned to each GBD 2013 MET cutpoint (600 MET-min/week, 3999 MET-min/week, 8000 MET-min) based on the estimated exposure distributions. Within each activity category, exposure was estimated to be uniformly distributed, allowing every possible MET value to be assigned a percentile cutoff. Percentiles from the relative risk studies were mapped to those assigned to the physical activity exposure distribution and the corresponding MET value was assigned as the cutoff for each relative risk category. After exposure metrics were standardized to MET-minutes/week for each study, Bayesian meta-regressions were used to generate continuous risk curves for each outcome.

Age-specific relative risks were generated for cardiovascular outcomes by linearly extrapolating the natural log of the relative risk to equal 1 at age 110, whereby the dependent variable is the ln (RR) and the independent variable is the mean or median age of study participants (i.e. mean or median age at baseline, whichever is reported, plus average years of follow-up/2, pooled across all component studies to get a single age midpoint for each outcome).

Metabolic risks

High fasting plasma glucose

For cardiovascular disease, epidemiological studies have shown that relative risks associated with high fasting plasma glucose (FPG) decline with the log (RR) having an approximately linear relationship with age, approaching a value of 1 between the ages 100 and 110. Thus we estimated age-specific RRs of FPG for cardiovascular outcomes using DisMod-MR 2.0 meta-regressions of pooled epidemiological studies with log (RR) as the dependent variable and median age at event as the independent variable with an intercept at age 110. Morbidity and mortality directly caused by diabetes was considered directly attributable to FPG. The main difference between 2010 and 2013 was the use of DisMod-MR 2.0 meta-regression instead of linear regression to impute for GBD age groups.

High total cholesterol

We estimated age-specific RRs of cholesterol for IHD using DisMod-MR 2.0 meta-regressions of pooled epidemiological studies with log (RR) as the dependent variable and median age at event as the independent variable with an age intercept (RR equals 1) at age 110. For total cholesterol and ischemic stroke, a similar approach was used, except that there was no age intercept at age 110, due to the fact that there was no statistically significant relationship between total cholesterol and stroke after age 70 with a mean RR less than one. We assumed that there is not a protective effect of high cholesterol and therefore did not include an RR for 80+.

High systolic blood pressure

Relative Risks for chronic kidney disease are from the Renal Risk Collaboration meta-analysis of 2.7 million individuals in 106 cohorts. For other outcomes, we used data from two pooled epidemiological studies: the Asia Pacific Cohort Studies Collaboration (APCSC) and the Prospective Studies Collaboration (PSC). For cardiovascular disease, epidemiological studies have shown that the RR associated with SBP declines with age, with the log (RR) having an approximately linear relationship with age and reaching a value of 1 between the ages of 100 and 120. We used DisMod-MR 2.0 meta

regressions of pooled epidemiological studies to estimate age-specific RRs of SBP for cardiovascular outcomes.

In order to be consistent with the relative risk values, we adjusted the variance of systolic blood pressure for regression dilution bias. Measurement error in BMI is not significant and micro-data were unavailable for these adjustments for FPG and cholesterol. Two main sources of error include measurement error, which is estimated by multiple measurements in one visit, and temporal noise, which represents variation across time, for example, between days, seasons, and years. It is assumed that measurement and other sources of noise (referred to here as temporal), attenuate the effect size of systolic blood pressure on cardiovascular disease. This is corrected for by converting blood pressure to the "usual" value, taking out the measurement error and temporal variation. We estimated the proportion of measurement error and temporal variation using a mixed effect analysis on individual records with multiple measurement in five studies including National Health and Nutrition Examination Survey, China Longitudinal Healthy Longevity Survey, Indonesia Family Life Survey, Philippines Cebu Longitudinal Health and Nutrition Survey, Mexican Family Life Survey, and China Health and Retirement Longitudinal Survey. In order to control for an aging effect in follow-up time, we included a fixed effect indicating age at the time of systolic blood pressure measurement in addition to sex:

$$y_{ijrt} = \beta_1 * sex_i + \beta_i * Ind(age_i) + \varepsilon_i + \varepsilon_r + \varepsilon_t$$
 equ. 19

i.. n: individual participants

 y_{iirt} : r^{th} measurement of SBP individual i; at age j; at time (year) t

 sex_i = Individual *i*'s gender (indicator variable for sex)

 β_1 : Fixed effect coefficient for sex

 β_i = fixed effect coefficient for age j

 ε_i : Individual error (between individual variance)

 $arepsilon_r$: Random effect across multiple measurements nested in each individual (intra-individual)

 ε_t : Random effect across time nested in each individual (temporal)

Measurement error, represented by the variance of ε_r , significantly varies across studies. Fortunately, the measurement error has already been controlled for because the majority of surveys report the average of multiple measurements for SBP. The size of temporal source variance compared to the total variance minus measurement error was quite stable across studies and was used for estimating variance to get the variance of the usual level. We corrected the standard deviation of SBP exposure distribution by multiplying the square root of the proportion of temporal variance to total variance after taking out the measurement error for each site and used the average of age-specific values across different studies as a universal correction multiplier to standard deviation of SBP distribution for very country, sex, and year.

Correction factor =
$$average\left(\left(\frac{var(\varepsilon_t)}{var(\varepsilon_t)+var(\varepsilon_i)}\right)^{1/2}\right)$$
 equ. 20

The final correction values are printed in Web Table 7 which, summarizes the relative risks used by age and sex for each risk factor for each outcome.

High body-mass index

For high body-mass index (BMI) modelling in GBD 2013, we disaggregated relative risks by menopausal status and region because there has been evidence that a differential impact is playing out (Bhaskaran et al; Renehan et al). ^{45,64} These studies have found that BMI has a protective effect for breast cancer in premenopausal women in non-Asian regions, but has a positive association in post-menopausal women. In Asia-Pacific, BMI did not have a protective effect in pre-menopausal women and the association was stronger in this region for both pre- and post-menopausal women Thus, we calculated region-specific relative risks for women ages 25-50 (pre-menopausal) and women ages 50-80+ (post-menopausal).

In addition, we conducted our own meta-analysis to update the relative risks for BMI and all of the site-specific cancers from GBD 2010. In our meta-analysis, we included all of the component studies included in Renehan et al's 2008 meta-analysis, as well as Bhaskaran et al's large UK cohort study. 45,64 In addition to updating the relative risks for the existing site-specific cancers, we also looked at five additional cancers (liver, cervix, ovarian, leukemia and thyroid). Cervical cancer was ultimately excluded due to a paucity of studies. Ovarian, leukemia, thyroid and liver cancers were all added as outcomes and the relative risks included a combination of component studies from existing meta-analyses and large cohort studies.

Low bone mineral density

In GBD 2013, low bone mineral density (BMD) is a continuous variable measured by dual-x-ray-absorptiometry (DXA) at femoral neck (FN) and is presenting in g/cm2 after standardizing for the brand of densitometer. Several changes happened in the strategy of estimation of attributable burden to low bone mineral density:

First, we used 980 data points in 2013, which was higher than 2010 (860 data points). We had data points from all regions except Andean Latin America, Central Sub-Saharan Africa, Eastern Sub-Saharan Africa and Oceania.

Second, four main changes happened in the estimation strategy.

In GBD 2010, only fractures due to "falls" were considered as the outcome of low bone mineral density. However, low BMD can increase risk, multiplicity and complexity of fractures even in high impact trauma. So, we generalized fracture outcomes to the following list of mechanisms of injuries:

Cause name
Transport injuries
Road injuries
Pedestrian road injuries
Cyclist road injuries
Motorcyclist road injuries
Motor vehicle road injuries
Other road injuries
Other transport injuries
Falls
Exposure to mechanical forces
Other exposure to mechanical forces

Animal contact
Non-venomous animal contact
Interpersonal violence
Assault by other means
Exposure to forces of nature

We recalculate relative risks per 0.1 g/cm² decrease in BMD from the Johnell's meta-analysis to cover all 40 years or older individuals and to reflect all kinds of fractures instead of the osteoporotic fractures.¹⁰³ The definition of osteoporotic fractures is vague and is mainly based on clinical impression.

For the TMREL, we used the 99th percentile of age-sex subgroups of the National Health and Nutrition Examination Survey (NHANES) III studies between 2005-2010 data instead of 90th percentiles used in GBD 2010 (Sànchez-Riera et al. 2014). This is specifically important in older ages when a large percentage of people experience low bone mineral density and even a 90th percentile is not necessarily enough to protect people from osteoporotic fractures.

In GBD 2010, deaths from falls that involved hip or vertebra fractures were considered as attributable to low BMD. Those with a mention of concurrent head or internal injury were excluded. In GBD 2013, deaths from the extended cause list (see above) that involved hip, femur, vertebra, pelvis, skull and sternum and/or ribs were attributed to low BMD. We excluded those deaths if were concurrent with other life-threatening injuries including moderate or severe traumatic brain injury (TBI), long term sequelae for TBI, severe chest Injury, internal hemorrhage in abdomen or pelvis, crush injury, multiple crashes, amputation of lower or upper limbs, drowning, asphyxiation, acute poisoning, burns >=20% total body surface area or >= 10% total body surface area if head/neck or hands/wrist involved and lower airway burns.

Low glomerular filtration rate

Age-specific relative risks for outcomes of ischemic heart disease, stroke, and peripheral vascular disease were calculated for low glomerular filtration rate (eGFR) using combined cohort (14 cohorts, n = 135,484) random effects meta-analysis. RRs per exposure categories of GFR <15ml/min/1.73m², 15-30 ml/min/1.73m², and 30-60 ml/min/1.73m² were determined. Relative risks were adjusted for traditional Framingham risk factors of age, gender, total cholesterol, high-density lipoprotein, diabetes mellitus status, smoking history, and systolic blood pressure. The TMREL risk of eGFR>60ml/min/1.73m² was based on epidemiological studies indicating increased risk of cardiovascular events secondary to GFR decline to occur below this threshold. RRs for gouty arthritis secondary to reduced GFR exposure were extracted from epidemiological studies.

Changes were also made to the eGFR relative risk model. To be consistent with other risk-CVD outcome pairs included in GBD, we wanted to create RRs that were age specific such that at age 110, there was no excess risk. We decided to do a meta-regression with a slope for each eGFR category, using age-specific data from the original studies. Originally, the meta-regression had been shifted by 110, forcing the regression line through the origin. With a small number of data points, this was especially problematic for peripheral vascular disease (PVD), where our predicted values were extremely high, especially among the younger age groups.

Rather than shifting the line by 110, we instead connected the line through an x-intercept at 110 with a small amount of uncertainty. This new meta-regression model fit the raw data much better than it had previously, especially for PVD. Although we are still faced with the limitations of very little data related to eGFR and the various CVD outcomes, this meta-regression model is much improved.
